Relationship between Primary Nodal Generalized Osteoarthritis with Tissue Antigens HLA-A and HLA-B in the Western Black Sea Region of Turkey

Cemal Taslıgil¹, Sirzat Cogalgil¹, Esra Tug², Burak Tonuk¹, Ozlem Sahin¹ and Dilek Dogruer²

Abstract

Objective To investigate the relationship between patients diagnosed with nodal generalized osteoarthritis (NGOA) and tissue antigens HLA-A and HLA-B in the Western Black Sea Region of Turkey.

Patients and Methods Forty-six patients with NGOA (64.74±8.46) and 60 controls (62.32±6.8) were included in the study. Inclusion criteria were: (i) stage 2 and higher OA of the hand and knee based on the Kellgren-Lawrence classification, and (ii) stage 2 and higher lumbar disc degeneration according to Lawrence classification. Family histories were taken from patients. HLA-A and HLA-B were typed by PCR using sequence specific primer.

Results The frequencies of HLA-A*02 and HLA-B*38 were 58.7% and 15.2%, respectively, in patients with NGOA, and there was a statistically significant relationship between the disease and HLA-A*02 and HLA-B*38. The relationship between positive family history and HLA-B*44 allele was also statistically significant. In the control group, the frequency of HLA-A’29 was 11.7% and it was statistically significant.

Conclusion To our knowledge this is the first study to demonstrate the epidemiologic association between HLA-A*02 and HLA-B*38 with NGOA in our population. We conclude that, HLA-B*44 positivity may be associated with familial NGOA and HLA-A’29 may be a preventive factor against NGOA.

Key words: primary nodal generalized osteoarthritis, HLA-A alleles, HLA-B alleles, tissue antigens

Introduction

Osteoarthritis (OA) is the most common age-related joint disorder, which develops as a result of the imbalance between the destruction and reconstruction of joint cartilage and subchondral bone (1). It was described by Kellgren and Moore in 1952 (2). It is called generalized OA if 3 or more joints are affected. Nodal generalized OA (NGOA) is a subset characterized by polynuatal interphalangeal and thumb base OA, female preponderance, early inflammatory component, and Heberden node formation; of all OA subsets, familial tendency is particularly recognized (1). OA is a dynamic process comprised of destruction and reconstruction, triggered by different biochemical and mechanic factors. Commonly it starts with no apparent reason and is referred to as idiopathic or primary OA. It may be hereditary or develop secondarily after joint trauma, infection, metabolic or neurological disease. The molecular pathogenesis is not fully understood, although genetic, environmental, metabolic and biomechanical factors seem to contribute to the pathogenesis (3).

The Human Leukocyte Antigen (HLA) system is very informative for population genetics because it is widely polymorphic and includes tightly linked loci, whose antigens are a key link in the immune response. Population analysis in various regions of the world provides grounds for investigation of the linkage between HLA antigens and various disor-
Black Sea region of Turkey. The relationship between the patients diagnosed with NGOA and HLA in the Turkish population. In this study, we aimed to investigate the relationship between NGOA and HLA in the Turkish population (11), but to our knowledge, there is no study that was reported (9, 10). A few reports are available in the Turkish literature (6). Despite marked familial predisposition, genetic markers in NGOA have been investigated in a few studies. Only four studies have presented data on the frequencies of HLA antigens (7, 8). One of these studies reported an increased frequency of HLA-A*01B08 (7) and another reported an increased frequency of HLA-B*08 while two studies found no relation (8). The distribution of HLA antigens in several ethnic groups in the world has been reported (9, 10). A few reports are available in the Turkish population (11), but to our knowledge, there is no study that shows the relationship between NGOA and HLA in the Turkish population. In this study, we aimed to investigate the relationship between the patients diagnosed with NGOA and tissue antigens HLA-A and HLA-B in the Western Black Sea region of Turkey.

Materials and Methods

I. Patients

Forty-six patients with NGOA, aged between 42 and 79 years (mean age 64.74±8.46 years), who presented with hand or knee OA were enrolled in this study. They were all diagnosed based on the American College of Rheumatology criteria for the classification of hand or knee OA (12). Radiographic staging was made for lumbar OA. Sixty healthy volunteers in the age range of 50 and 77 years (mean age 62.32±6.8 years) without clinical or radiological signs of hand or knee OA served as controls. People from the same region were chosen for the control group because of ethnic and geographic relevancy. Human Clinical and Laboratory Research Local Ethics Committee approved the study. All patients were informed about the study, and their consent was taken for the diagnostic and molecular testing of HLA.

Hand and knee radiographs were all reviewed according to Kellgren and Lawrence scoring system for knee and hand and Lawrence classification for lumbar region (13), by two consultant radiologists who had no information about the patients’ clinical situation.

II. Design

Radiological assessment

Each subject had postero-anterior plain radiographs of both hands at the time of evaluation. Radiographs of both knees were taken antero-posteriorly while the subjects were standing, feet were 10° externally rotated, knees and thighs were in contact with the vertical platform anteriorly and x-ray device was angled 10° vertically and caudally. Hand and kneesradiographs were all reviewed by two consultant radiologists. Radiographs were graded according to the criteria described by Kellgren and Lawrence (13) in the Atlas of Standard Radiographs. OA was graded as follows: 0=no OA, grade 1=doubtful OA, grade 2=minimal OA, grade 3=moderate OA, and grade 4=severe OA. Definite hand and knee OA was diagnosed when the score was ≥2.

Lumbar vertebre (L1-L5) radiographies were taken in the lateral decubitus position and scored according to Lawrence classification (13). Definite lumbar OA was diagnosed in the presence of a grade ≥2.

Patients who had OA in three or more areas were diagnosed with generalized OA (14).

Inclusion criteria

1. Presence of hand, knee and lumbar OA according to American Rheumatism Association,
2. Radiographically stage 2 or higher OA according to Kellgren and Lawrence Scale,
3. Age ≥40, being postmenopausal for females,
4. No pathological findings in blood samples in both patient and control groups.

Exclusion criteria

1. Presence of an inflammatory disease such as rheumatoid arthritis, psoriatic arthritis,
2. Presence of erosive OA and chondrocalcinosis,
3. Patients who had previous orthopedic surgery or fracture,
4. Patients who had secondary OA (post-traumatic, metabolic, and inflammatory rheumatic disease),
6. Age <40,
7. Smoking or alcohol consumption.

Sex, age, weight, and height of all subjects were recorded. Pedigrees were drawn for all patients and finger nodules were asked for patients’ parents, children and siblings. Complete blood count, biochemical tests, erythrocyte sedimentation rate, CRP and rheumatoid factor (RF) were ordered for all subjects. Body mass index (BMI) was calculated and subjects were divided into six groups as normal (<25 kg/m²), borderline obesity (25-27 kg/m²), mild obesity (27-30 kg/m²), moderate obesity (30-35 kg/m²), critical obesity (35-40 kg/m²) and severe obesity (>40 kg/m²) (15).

III. HLA typing

Three mL of venous blood samples were collected in EDTA coated tubes from each of the 106 subjects and genomic DNAs were extracted by “QIAamp DNA Blood Mini Kit” (Qiagen, Germany). Typing of HLA class I (HLA-A and -B) was performed using HLA-A Low Resolution (Res.) Sequence Specific Primer (SSP) and HLA-B Low Res. SSP (Olerup SSP AB, Sweden) with a thermocycler (Takara, Japan) according to the guidelines of the manufacturer.

IV. Statistical analysis

“SPSS (Statistical Package for Social Sciences) for Windows 17.0” was used for statistical analysis of the data. Continuous variables were expressed as mean ± standard deviation. Continuous variables were compared with t-test, categorical variables were compared with chi square test. Post hoc Tukey test and ANOVA were used for comparing parametric variables between groups. Kruskal-Wallis and chi square tests were used for comparing nonparametric variables and percentages. Statistical significance was accepted as p<0.05 for all tests.

Results

Demographic characteristics of both groups are presented in Table 1. There was no significant difference in age and gender (p>0.05) between the two groups but there was a significant difference between the two groups for BMI (p<0.05) (Table 1).

Radiographic staging of nodal hand OA patients and the relationships between BMI and stage are presented in Table 2. There was a no significant relation between nodal hand OA and BMI (p>0.05).

The most commonly determined HLA-A alleles were HLA-A*02, HLA-A*24 and HLA-A*11, with frequencies of 58.7%, 30.4% and 23.9%, respectively, whereas in the patient group, the most common HLA-B alleles were HLA-B*35, HLA-B*15 and HLA-B*38, with frequencies of 39.1%, 17.4% and 15.2%, respectively. Comparison of the groups revealed significant differences in HLA-A*02 and HLA-B*38 (p<0.05). While HLA-A*29 was found in 11.7% of the patient group, it was not identified in the control group (p<0.05).

When we compared the disease severity with HLA-A and B alleles, we found no significant relationship between HLA-A alleles and stages while HLA-B*51 allele was significantly related to stage 3 of the disease (p<0.05).

Six subjects in the patients group with HLA-B*44 allele had a positive family history and there was a statistically significant relationship between HLA-B*44 and positive family history (p<0.05). There was no relation between other HLA alleles and family history (p>0.05). HLA-A and HLA-B alleles determined in both groups are shown in Table 3.

Discussion

NGOA is diagnosed in the presence of OA in three or more joints and Heberden and Bouchard nodules, which occur as a result of interphalangeal joint involvement. Genetics is known to be a component of the etiology/pathogenesis of NGOA. Familial predisposition lends support to a genetic component (20). It has been argued that OA is not the result of a single genetic anomaly but rather it is under the influence of multiple genes and environmental factors. Genetic analyses have shown that ADAM12, BMP2, CD36, COX2, NCOR2 genes are related to OA and associations of loci on the 2nd, 4th, 6th, 7th, 11th, 16th chromosomes and X chromos...
mosome with OA have been demonstrated (21). Relationships between different HLA alleles and OA or OA variants are also known. Indeed, the findings of Saito and colleagues (22) who examined the synovial tissue of the medial and lateral compartments of the patients with knee OA histochromically and showed more antibodies against type II collagen, and CD68, CD4 and HLA-DR positivity on the medial surface, corroborates the relationship between HLA and this disease.

Wakitani et al (23) showed that the frequencies of HLA-B*02 and HLA-Cw4 in Japanese patients with NGOA were higher. Pattrick et al (24) found an increase in the frequencies of HLA-A*01 and HLA-B*08 in NGOA patients and they reported a possible relation between A1B8 haplotype and NGOA. Linkage analysis in a healthy Turkish population showed that the most frequent HLA haplotypes in that population were B35Cw4, A1B8 and B27Cw2, with A1B8 haplotype being more frequent in the western Turkey region (16).

With frequencies of 58.7% and 39%, HLA-A*02 and HLA-B*35, respectively, were the most common alleles in NGOA patients in our study. Compared to the control group, HLA-A*02 was statistically significant. However, such a significant relation was not observed in HLA-B*35 allele between two groups. HLA-B*38 was the third most frequent allele (15.2%) and there was a significant difference between the control and patient groups (Table 3). Despite the fact that previous studies conducted on a Turkish population showed that, with a frequency of 38.2%, HLA-A*02 was the most common HLA-A allele, its frequency among NGOA patients in our region was higher than the mean frequency of HLA-A*02 in the Turkish population (24.7%) (16). Arnaiz-Villena et al (18) reported the frequency of HLA-B*35 (39%) among NGOA patients in our region (58.7%) was above the mean frequency in Turkey. The most common HLA-B allele in our region was HLA-B*02 was statistically significant. However, such a significant relation was not observed in HLA-B*35 allele between two groups. HLA-B*38 was the third most frequent allele (15.2%) and there was a significant difference between the control and patient groups (Table 3). Despite the fact that previous studies conducted on a Turkish population showed that, with a frequency of 38.2%, HLA-A*02 was the most common HLA-A allele, its frequency among NGOA patients in our region (58.7%) was above the mean frequency in Turkey. The most common HLA-B allele in our region was HLA-B*35 (39%), though this allele is the second most common allele in the Turkish population (43.5%) (16). Arnaiz-Villena et al (18) reported the frequency of HLA-B*35 allele in the Turkish population as 3.3%. The frequencies of the same HLA alleles among NGOA patients in our region were higher than the means of Turkey. Tokgoz et al (16) revealed that, in terms of the HLA data, except for minor differences, the populations in geographic regions of Turkey were homogenous. However, lower frequencies of these alleles found by Tokgoz and colleagues may be attributed to the fact that they covered all the Black Sea region. In fact, it would be more appropriate to

† statistically significant p value. ** Gene frequency of related allele in Turkish population (16,17,18,19).
assess Eastern and Western Black Sea regions separately. Our results suggest that the distribution of the HLA alleles reported in the Turkish population is not homogeneous.

In contrast to the results of Patrnick et al (24), we did not find any relation between HLA-A*01 and HLA-B*08 alleles in the patient group and NGOA. On the other hand, our results were similar to those of Clague et al (25) who showed a relationship between HLA-A*02 and NGOA in a British population. Our literature review did not produce any study reporting a relation between NGOA and HLA-B*38. This suggests that the relationship may be specific to patients with NGOA in our region. Moreover, this result supports that HLA class I antigens can show a different clinic correlation in different ethnic groups.

Although there are a couple of differences in antigen frequencies among geographic regions, A*02, A*09 and A*01 are the most common A-locus antigens (11). When the Turkish population is compared to European Caucasoids, few differences in antigen frequencies can be seen. In the Turkish population, the frequencies of HLA-A*01, *02 and *09 are higher. The frequencies of HLA-A are similar in Turkish, European Caucasoid and Greek populations. In Japanese Orientals, the frequency of HLA-A*01 is lower than other populations (16). In the present study, in addition to being the most frequent HLA allele, the frequency of HLA-A*02 was above the mean of Turkey and so was *01 allele (19.6%). *09 allele, on the other hand, was not determined in our study group.

Ersoy (11) revealed that the most common B locus antigens in Turks were B*05, B*35 and B*12. In the present study, we did not detect HLA-B*05 or B*12 while B*35 was the most common HLA-B allele (39.1%).

Relationships between hand OA and B35DQ1, B40DQ1 and DR2DQ1 haplotypes and roles of A24B18 or A25B18 and B18DR5 haplotypes as protective factors against nodal hand OA have been reported (26). While HLA-A*29 allele was absent among the subjects of our patient group, it was found in 11.7% of the subjects in the control group and the difference was statistically significant. In the light of these results, we conclude that HLA-A*29 allele, which was not found to be significant in previous studies, has a protective role against NGOA in our region. Furthermore, there was a statistically significant relation between disease severity and HLA-B*51 allele. Individuals with HLA-B*51 allele had stage 3 NGOA. Therefore, one can conclude that HLA-B*51 allele accompanies osteoarthritis with a more severe course.

Previous studies reported that HLA-A*02 allele was the most frequent HLA-A subgroup among all populations whereas HLA-A*24 allele is present only in Caucasians but not in African-Americans or Asians (27). In our control group, the frequencies of HLA-A*02, HLA-A*03 and HLA-B*40 alleles were 40%, 30%, and 15.3%, respectively, and these are significantly higher than those reported by other studies from this country (16, 17).

In NGOA patients, familial predisposition in the presence of degenerative nodules of the hand joints has long been known (15). A familial tendency in concomitant hand and knee OA has also been reported (6). In a study on dizygotic and monozygotic female twins with hand and knee OA, Spector et al (28) investigated the effects of genetic and environmental factors and reported that the influence of genetic factors, independent of environmental and demographic factors, varied between 39-95%. In the present study, all patients with HLA-B*44 allele had a positive family history. Hence, it is possible to conclude that a strong familial predisposition exists in NGOA patients with HLA-B*44 allele.

In the present study, we found that HLA-A*02 and HLA-B*38 alleles can be related to NGOA, an association that has not been reported elsewhere. We found some evidence that suggests HLA-A*29 allele having a protective role in NGOA development and HLA-B*51 allele is related to the severity of the disease. Further, we found that there is a strong familial predisposition among patients with NGOA and HLA-B*44 allele.

Similar studies must be carried out in larger groups and in different geographical regions to determine the exact relation between NGOA and HLA haplotypes since this is an autoimmune disease and shows a multifactorial inheritance.

The authors state that they have no Conflict of Interest (COI).
